How innovation occurs in evolution of molecules

Peter Schuster

Institut für Theoretische Chemie und Molekulare Strukturbiologie der Universität Wien

Evolutionary innovation

Praha, 30.05.2002

Darwinian principle is based on three functions:

- Reproduction efficiency expressed by fitness of phenotypes.
- Variation of genotypes through imperfect copying and recombination.
- Selection of phenotypes based on differences in fitness.

Two additional features are required:

- Large reservoirs of genotypes and sufficiently rich repertoires of phenotypes.
- Mapping of genotypes into phenotypes with suitable properties.

The **genotypes** or **genomes** of individuals are DNA or RNA sequences. They are changing from generation to generation through mutation and recombination. Species are reproductively related ensembles of individuals.

Genotypes unfold into **phenotypes**, being molecular structures, viruses or organisms, which are the targets of the evolutionary selection process.

The most common mutations are **point mutations**, which consist of single nucleotide exchanges. The **Hamming distance** of two sequences is the minimal number of single nucleotide exchanges that mutually converts the two sequence into each other.

Random graph theory is used to model and analyse the relationships between sequences and secondary structures of RNA molecules, which are understood as mappings from sequence space into shape space. These maps are non-invertible since there are always many orders of magnitude more sequences than structures. Sequences folding into identical structures form neutral networks. A neutral network is embedded in the set of sequences that are compatible with the given structure. Networks are modeled as graphs and constructed by random choice of vertices from the space of compatible sequences. The theory characterizes neutral networks by the mean fraction of neutral neighbors (λ). The networks are connected and percolate sequence space if the fraction of neutral nearest neighbors exceeds a threshold value $(\lambda > \lambda^*)$. Below threshold $(\lambda < \lambda^*)$, the networks are partitioned into a largest "giant" component and several smaller components. Structures are classified as "common" or "rare" according to the sizes of their pre-images, i.e. according to the fractions of sequences folding into them. The neutral networks of any pair of two different common structures almost touch each other, and, as expressed by the conjecture of shape space covering sequences folding into almost all common structures, can be found in a small ball of an arbitrary location in sequence space. The results from random graph theory are compared to data obtained by folding large samples of RNA sequences. Differences are explained in terms of specific features of RNA molecular structures. © 1997 Society for Mathematical Biology

THEOREM 5. INTERSECTION-THEOREM. Let s and s' be arbitrary secondary structures and C[s], C[s'] their corresponding compatible sequences. Then,

$C[s] \cap C[s'] \neq \emptyset.$

Proof. Suppose that the alphabet admits only the complementary base pair [XY] and we ask for a sequence x compatible to both s and s'. Then $j(s, s') \cong D_m$ operates on the set of all positions $\{x_1, \ldots, x_n\}$. Since we have the operation of a dihedral group, the orbits are either cycles or chains and the cycles have even order. A constraint for the sequence compatible to both structures appears only in the cycles where the choice of bases is not independent. It remains to be shown that there is a valid choice of bases for each cycle, which is obvious since these have even order. Therefore, it suffices to choose an alternating sequence of the pairing partners X and Y. Thus, there are at least two different choices for the first base in the orbit.

Remark. A generalization of the statement of theorem 5 to three different structures is false.

Sequence of mutants from the intersection to both reference ribozymes

From sequences to shapes and back: a case study in RNA secondary structures

SUMMARY

RNA folding is viewed here as a map assigning secondary structures to sequences. At fixed chain length the number of sequences far exceeds the number of structures. Frequencies of structures are highly nonuniform and follow a generalized form of Zipf's law: we find relatively few common and many rare ones. By using an algorithm for inverse folding, we show that sequences sharing the same structure are distributed randomly over sequence space. All common structures can be accessed from an arbitrary sequence by a number of mutations much smaller than the chain length. The sequence space is percolated by extensive neutral networks connecting nearest neighbours folding into identical structures. Implications for evolutionary adaptation and for applied molecular evolution are evident: finding a particular structure by mutation and selection is much simpler than expected and, even if catalytic activity should turn out to be sparse in the space of RNA structures, it can hardly be missed by evolutionary processes.

Figure 4. Neutral paths. A neutral path is defined by a series of nearest neighbour sequences that fold into identical structures. Two classes of nearest neighbours are admitted: neighbours of Hamming distance 1, which are obtained by single base exchanges in unpaired stretches of the structure. and neighbours of Hamming distance 2, resulting from base pair exchanges in stacks. Two probability densities of Hamming distances are shown that were obtained by searching for neutral paths in sequence space: (i) an upper bound for the closest approach of trial and target sequences (open circles) obtained as endpoints of neutral paths approaching the target from a random trial sequence (185 targets and 100 trials for each were used); (ii) a lower bound for the closest approach of trial and target sequences (open diamonds) derived from secondary structure statistics (Fontana et al. 1993a; see this paper, §4); and (iii) longest distances between the reference and the endpoints of monotonously diverging neutral paths (filled circles) (500 reference sequences were used).

Chemical kinetics of replication and mutation as parallel reactions

The molecular quasispecies in sequence space

The **RNA model** considers **RNA sequences** as **genotypes** and simplified **RNA structures**, called **secondary structures**, as **phenotypes**.

Variation is restricted to **point mutations**.

The **mapping** from genotypes into phenotypes is many-to-one. Hence, it is redundant and not invertible.

Genotypes, i.e. RNA sequences, which are mapped onto the same phenotype, i.e. the same RNA secondary structure, form **neutral networks**. Neutral networks are represented by graphs in sequence space.

RNA secondary structures and their properties

RNA secondary structures are **listings of** Watson-Crick and GU wobble **base pairs**, which are free of knots and pseudokots. Secondary structures are **folding intermediates** in the formation of full three-dimensional structures.

Neutral networks of small RNA molecules can be computed by exhaustive folding of complete sequence spaces, i.e. all RNA sequences of a given chain length. This number, $N=4^{\circ}$, becomes very large with increasing length, and is prohibitive for numerical computations.

Neutral networks can be modelled by **random graphs** in sequence space. In this approach, nodes are inserted randomly into sequence space until the size of the pre-image, i.e. the number of neutral sequences, matches the neutral network to be studied.

Transition inducing point mutations

Neutral point mutations

Neutral genotype evolution during phenotypic stasis

"...Variations neither useful not injurious would not be affected by natural selection, and would be left either a fluctuating element, as perhaps we see in certain polymorphic species, or would ultimately become fixed, owing to the nature of the organism and the nature of the conditions.

Charles Darwin, Origin of species (1859)

Fitness

Genotype Space

Evolution in genotype space sketched as a non-descending walk in a fitness landscape

A random sequence of **minor** or continuous **transitions** in the relay series

A random sequence of minor or continuous transitions in the relay series

Minor or continuous transitions: Occur frequently on single point mutations

Probability of occurrence of different structures in the mutational neighborhood of tRNA^{phe}

In silico optimization in the flow reactor: Uninterrupted presence

Reconstruction of a major transitions 36 š 37 (š 38)

Final reconstruction 36 š 44

Probability of occurrence of different structures in the mutational neighborhood of tRNA^{phe}

In silico optimization in the flow reactor: Major transitions

In silico optimization in the flow reactor

Transition probabilities determining the presence of phenotype $S_k^{(j)}$ in the population

Calculation of transition probabilities by means of a birth-and-death process with immigration

Statistics of evolutionary trajectories

Three important steps in the formation of the tRNA clover leaf from a randomly chosen initial structure

Stable tRNA clover leaf structures built from binary, GC-only, sequences exist. The corresponding sequences are readily found through inverse folding. Optimization by mutation and selection in the flow reactor has so far always been unsuccessful.

The neutral network of the tRNA clover leaf in GC sequence space is not connected, whereas to the corresponding neutral network in AUGC sequence space is very close to the critical connectivity threshold, \hat{c}_{rr} . Here, both inverse folding and optimization in the flow reactor are successful.

The success of optimization depends on the connectivity of neutral networks.

Main results of computer simulations of molecular evolution

• Individual trajectories are not reproducible. The sequences of the target structures obtained and the relay series were different. Nevertheless, solutions of comparable or the same quality are almost always achieved.

• **Transitions** between molecular phenotypes represented by RNA structures can be classified with respect to the induced structural changes. **Minor transitions** of high probability of occurrence are opposed by **major transitions** of low probability.

• **Major transitions** represent the relevant **structural innovations** in the course of molecular evolution.

- The number of **minor transitions** decreases with increasing population size.
- The number of **major transitions** or **structural innovations** is approximately constant for given start and stop structures.
- Not all structures are accessible through evolution in the flow reactor.
